CSC 425 – Time Series Analysis

# **Retail Sales Data**

**Final Project** 

Bill Qualls Laura Floyd 3/13/2013

## NON-TECHNICAL SUMMARY

The goal of the analysis was to model retail sales data for clothing & accessories stores, given a dataset of monthly sales data from January 1992 through December 2012. The data set contains 252 observations, which include clothing and accessory store monthly sales data (in millions), as reported by retailers selected by a rigorous selection process by the US Government, ensuring sample representivity for the US. (More detail: <a href="http://www.census.gov/retail/mrts/how\_surveys\_are\_collected.html">http://www.census.gov/retail/mrts/how\_surveys\_are\_collected.html</a>)

The data appears to have an increasing average value over time, which is to be expected given inflation, at the very least. Additionally, there's a sharp spike in sales data around the holiday season every year in December. In order to properly predict future sales data, this increasing mean and sharp spike in December needs to be removed. A few transformations were made to the data to make it suitable for modeling. Initially, the log is taken for each datapoint. This will (with later transforms) serve to stabilze the variation in the data. Next, by taking the change in log value month-to-month (rather than the actual value every month), we can eliminate the upward trend of the data over time. Finally, if we take the difference between the current month and a month twelve months out, then the spike in December is accounted for.

The final model fitted to our data takes these transformations into account and fits a model to the dataset that predicts the values well. Our residuals, or the difference between the actual data point and our predicted data point, show a relatively consistent pattern across all points in our data; our model does not favor any set of values in the data. We've predicted the sales data for 2013, and in early returns for January that the government has begun to collect, the value they have reported is within our range of values.

In the chart below, the purple solid line in the first half of the chart are our actual values. The red dotted line is the predicted value, and the the brown dotted line (the "top" line) is the max prediction and the blue dotted line (the "bottom" line) is the minimum prediction. Our model follows the trend of the actual 2012 data well, and will ideally follow 2013 beyond January, as well.

## **TECHNICAL SUMMARY**

# DATASET

The dataset used for this analysis includes monthly sales data for clothing & accessories stores in the US from January 1992 through December 2012. There are 252 observations on sales data (in millions), as reported by retailers selected by a rigorous selection process by the US Government, ensuring sample representivity for the US. (More detail is available at

<u>http://www.census.gov/retail/mrts/how\_surveys\_are\_collected.html</u>). The variables present in the dataset are period (month) and value (sales data, in millions).

# **EXPLORATORY ANALYSIS**

Evaluating a plot of values over time, the data shows strong evidence of seasonality, with a sharp jump at the 12<sup>th</sup> month in every year (understood to be a jump for holiday sales). Additionally, there appears to be a positive trend in the data, as well, with the mean increasing year over year.

Given the data is not adequate for analysis as-is, several steps are taken to clean and prepare the data for fitting a time series model:

- Given increasing average, the difference of the data is taken (value minus the first lag). The trend is gone, but there is still evidence of seasonality. (See Appendix, figure 2)
- Next, the lag12 difference is taken to account for seasonality. The trend and seasonality are both gone, but the variance is not constant. (See Appendix, figure 3)
- The log transform is computed on the original data in order to stabilize the variance. Trend and seasonality are still evident on the log transform. (See Appendix, figure 4)
- The difference is taken to account for the trend. (See Appendix, figure 5)
- Removed seasonality by taking the lag12 difference. Data now shows constant mean and variance, with no obvious trends or seasonality present. (See Appendix, figure 6)

As noted, taking the log transform, first difference in the data, followed by the 12<sup>th</sup> difference in the data removes all evidence of a trend as well as seasonality. The visual representation of this transformed data

shows all evidence of seasonality and trend removed, and it also appears to have a constant mean and variance, as well.

Visual tests of normality show that the data appears to be normally distributed, and more detailed tests evaluating normality, skewness, and kurtosis all show our data is normal. (See Appendix, section 1.8 for detailed tests of normality.)

Once the appropriate transformations of the data were identified and the resulting values on which to fit a time series model were normal, the model fitting process could begin.

#### **MODEL FITTING**

Given the type of seasonality seen in the data, the first model used as an attempt to fit the data is the Airline Model, or a seasonal model. The correlations of the differenced values are analyzed, and assumptions needed to use the Airline Model appear to be fulfilled: the data is highly correlated at lags 1, 11, 12, and 13.

All other autocorrelations in the data are zero, or in other words, are not statistically significant from zero.

The first attempt to fit the data is using an additive MA(1, 12, 13) on the differenced data. However, the residuals show evidence of serial correlations, which means the model is not an adequate fit.

|        | Autocorrelation Check of Residuals |    |            |                  |        |        |        |        |        |  |  |  |  |  |

| 36     | 162.05                             | 34 | <.0001     | -0.026           | 0.097  | -0.171 | 0.023  | 0.069  | -0.152 |  |  |  |  |  |
| 42     | 186.28                             | 40 | <.0001     | 0.149            | -0.067 | -0.158 | 0.108  | -0.116 | -0.085 |  |  |  |  |  |

Additionally, the residuals of this model have a high negative correlation at the 10<sup>th</sup> lag, which may be something to incorporate into the final model.

Several models were attempted via trial-and-error. Ultimately, the best fit model using our log transform variable is an ARIMA(1,2)x(10,12)12, which takes into the first and second difference as well as a  $10^{th}$  and  $12^{th}$  seasonal lag. All coefficients of this model are significant (values are significantly different from zero), which means all parameters used in the model are necessary and fit our dataset appropriately.

|           | Maximu   | um Likelihood Es | timation |                   |     |
|-----------|----------|------------------|----------|-------------------|-----|
| Parameter | Estimate | Standard Error   | t Value  | Approx<br>Pr >  t | Lag |
| MA1,1     | 0.16051  | 0.06596          | 2.43     | 0.0150            | 10  |
| MA2,1     | 0.47026  | 0.06215          | 7.57     | <.0001            | 12  |
| AR1,1     | -0.72471 | 0.06066          | -11.95   | <.0001            | 1   |
| AR1,2     | -0.40097 | 0.06020          | -6.66    | <.0001            | 2   |

The final model can be written as:

$$(1 - 0.725B + 0.401B^{2})X_{t} = (1 - 0.161B^{10})(1 - 0.470B^{12})a_{t}$$

# **RESIDUAL ANALYSIS AND MODEL DIAGNOSTICS**

Using the fitted model, our residuals are white noise (autocorrelations are not significantly different from zero), which shows no evidence of serial correlation. Additionally, the residuals appear to be relatively normally distributed, as well.

|        |            | A  | utocorrelation | Check | of Res | iduals   |          |        |        |

| 30     | 46.73      | 26 | 0.0075         | 0.035 | 0.028  | -0.115   | -0.050   | -0.064 | -0.191 |
| 36     | 50.41      | 32 | 0.0203         | 0.035 | 0.078  | -0.045   | -0.016   | 0.054  | -0.027 |
| 42     | 62.75      | 38 | 0.0070         | 0.103 | -0.087 | -0.118   | 0.024    | -0.100 | -0.005 |

These results further confirm that the fitted model adequately explains the time series found in the data.

### FORECAST ANALYSIS

Evaluating the trend of our data in 2012, our model appears to forecast at least the trend of the actual values rather well. Projecting ahead through 2013, the results our model generates are:

| Period  | Forecast | Lower 95% Conf Limit | Upper 95% Conf Limit |
|---------|----------|----------------------|----------------------|
| JAN2013 | 14936.14 | 14063.29             | 15848.42             |
| FEB2013 | 18155.60 | 17055.57             | 19307.25             |
| MAR2013 | 20399.92 | 19077.51             | 21788.94             |
| APR2013 | 19623.76 | 18183.13             | 21147.11             |

| OCT2013 | 19864.61 | 17923.25             | 21957.27             |
| NOV2013 | 22939.91 | 20665.29             | 25394.60             |
| DEC2013 | 33410.02 | 30001.74             | 37096.55             |

An advanced estimate for clothing & accessory store retail sales data for January 2013 (based on early reports from a small sampling of firms) was \$15,119 million (or \$15 billion). The actual value is well within the confidence interval for our forecast. At least for that one new data point, our model appears to predict the sales data well.

(http://content.govdelivery.com/attachments/USESAEI/2013/02/13/file\_attachments/190485/Advance%2BMonthly%2BSales%2Bfor%2BRetail%2Ba nd%2BFood%2BServices%2B%2528January%2B2013%2529.pdf)

Additionally, looking at the backtesting results of the selected model versus the simpler airline model, we see a marginally better MAFE, MSFE, and RMSFE.

Backtest of accepted model:

# ANALYSIS OF RESULTS AND DISCUSSION

As noted, our model assumptions appear to fit the sales data well. The first data point beyond our dataset for January 2013 (again, though not the true value, this is the predicted value based on actual results reported early) is well within our confidence range for predictions. Our parameters are all significant and our residuals appear to be white noise.

It should be noted that the first model (a simple, additive airline model MA(1,12,13)) was rejected because the residuals showed evidence of autocorrelation. Our selected model also has a lower MAFE, MSFE, and RMSFE than this rejected model. Despite our selected model being relatively simple, these results showed that the data needed more parameters than the most simple airline model provided. Additionally, the MAPE for our accepted model is 2.3%, whereas the MAPE of our rejected model is 2.4%.

Another rejected model had many more parameters and seemed to provide a better fit on the data, but the model failed to converge in the estimation process (likely due to being overparameterized). As seen in many cases of time series modeling, there may be multiple models that fit the data well (or some may have some diagnostics better than other models), which means there may be several models that might fit the data reasonably well, just as we've seen with this data set, as well.
